Report Overview

Non-common optical path interferometer is an interferometer that measures the difference in optical paths. It performs interference measurement by propagating two beams of light along different paths and merging them. The core idea of this interferometer is to use the superposition of waves to obtain the phase information of the waves, so as to deduce the physical quantities of interest in the experiment, such as distance and surface shape. In a non-common optical path interferometer, a slight deformation or displacement caused by the object under test will change the path length difference between the two beams of light, and this change will cause the interference fringes to move or deform. By observing and recording the changes in the interference fringes, the relevant physical quantities of the object under test can be calculated. Non-common optical path interferometers are widely used in many fields, including but not limited to three-dimensional scanning, optical surface measurement, precision manufacturing, etc. These applications all rely on the high precision and high sensitivity of non-common optical path interferometers, which can achieve accurate measurement of small changes in the object under test.
