Abstracts

At present, serological antibodies and electrophysiological examinations provide the main basis for the diagnosis of MG, including single-fiber electromyography (the highest sensitivity, about 99%), serum antibody detection (high specificity, ocular muscle type sensitivity is about 50%, systemic type 85%), repetitive electrical stimulation (lower sensitivity when detecting proximal muscles, about 76%). AchEI can be used to help support the diagnosis of MG, and based on its clinical response, it can indicate a positive response to long-term treatment, but its current application is limited due to objectivity defects and false positives. Edrophonium testing can cause life-threatening complications that may require urgent resuscitation and is currently/banned in Italy and several other countries. In contrast, the neostigmine trial was more safe and reliable.
