Hemophilia is a hereditary bleeding disorder, mainly caused by the lack or abnormality of coagulation factor VIII or coagulation factor IX, leading to coagulation dysfunction in patients. The symptoms of hemophilia patients are mainly reflected in three aspects: bleeding and bleeding-related symptoms, symptoms related to damage caused by bleeding, and treatment-related symptoms. The vast majority of hemophilia patients are male. The main clinical manifestations are spontaneous bleeding in joints, muscles, internal organs and deep tissues or difficulty in stopping after minor trauma. As a chronic disease, long-term or lifelong medication is the norm for patients with hemophilia. Early diagnosis and continuous care are crucial to reduce mortality.

Hemophilia can be divided into hemophilia A (FVII deficiency), hemophilia B (FIX deficiency), other coagulation factor deficiencies, inhibitor-positive hemophilia patients, etc. People with hemophilia often have a family history of bleeding. Among all patients with hemophilia, patients with hemophilia A account for 80%-85%, patients with hemophilia B account for 15%-20%, and patients with other hemophilia are extremely rare.

Coagulation factor replacement therapy is the current mainstay of treatment for hemophilia. The preferred drug for replacement therapy is genetically recombinant coagulation factor VIII or virus-inactivated blood-borne coagulation factor VIII. However, patients who frequently receive coagulation factor VIII replacement therapy are often accompanied by the production of alloneutral antibodies (inhibitors), making bleeding symptoms more difficult to control and the risk of fatal bleeding increasing. Currently, gene therapy is emerging as an effective long-term treatment for hemophilia.
