The report requires updating with new data and is sent in 48 hours after order is placed.

At present, serological antibodies and electrophysiological examinations provide the main basis for the diagnosis of MG, including single-fiber electromyography (the highest sensitivity, about 99%), serum antibody detection (high specificity, ocular muscle type sensitivity is about 50%, systemic type 85%), repetitive electrical stimulation (lower sensitivity when detecting proximal muscles, about 76%). AchEI can be used to help support the diagnosis of MG, and based on its clinical response, it can indicate a positive response to long-term treatment, but its current application is limited due to objectivity defects and false positives. Edrophonium testing can cause life-threatening complications that may require urgent resuscitation and is currently/banned in Italy and several other countries. In contrast, the neostigmine trial was more safe and reliable.
