LCD liquid crystal splicing is a new splicing technology that has emerged in recent years. The structure of LCD is to place liquid crystals between two parallel pieces of glass. There are many vertical and horizontal fine wires between the two pieces of glass. The rod-shaped crystal molecules are controlled to change direction by powering on or off, and the light is refracted to produce a picture. LCD is composed of two glass plates, about 1mm thick, separated by a 5?m uniform interval containing liquid crystal material. Because the liquid crystal material itself does not emit light, lamps are set on both sides of the display screen as light sources, and there is a backlight plate (or lighthomogenizing plate) and a reflective film on the back of the liquid crystal display screen. The backlight plate is composed of fluorescent materials that can emit light. Its main function is to provide a uniform background light source. The light emitted by the backlight plate enters the liquid crystal layer containing thousands of liquid crystal droplets after passing through the first polarization filter layer. The droplets in the liquid crystal layer are all contained in a tiny cell structure, and one or more cells constitute a pixel on the screen. Between the glass plate and the liquid crystal material is a transparent electrode, which is divided into rows and columns. At the intersection of the row and the column, the optical rotation state of the liquid crystal is changed by changing the voltage. The role of the liquid crystal material is similar to that of a small light valve. Around the liquid crystal material are the control circuit and the drive circuit. When the electrodes in the LCD generate an electric field, the liquid crystal molecules will be distorted, thereby refracting the light passing through them in a regular manner, and then being filtered by the second filter layer and displayed on the screen.
